### Random Walks on Graphs

## 1 Adjacency Matrices and Random Walks

### 1.1 The Adjacency Matrix, Counting Paths

Given a possibly-directed, unweighted graph G = (V, E) with |V| = n, |E| = m, its **adjacency matrix**  $A_G \in \{0, 1\}^{n \times n}$  is the matrix

$$A_G(i,j) = \begin{cases} 1 & (i,j) \in E \\ 0 & \text{otherwise.} \end{cases}$$

Her  $A_G(i, j)$  is the entry in the *i*th row and *j*th column. Note the diagonal entries are 0, assuming that as usual we have no self-edges.

**Running Example:** Consider the undirected "path graph" on 3 vertices, i.e. the two edges are (1, 2) and (2, 3). We have

$$A_G = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$

In general a matrix  $A \in \mathbb{R}^{n \times n}$  is a representation of a linear function from  $\mathbb{R}^n$  to  $\mathbb{R}^n$ .

In this case, we can picture the vertices of the graph as the basis vectors in  $\mathbb{R}^n$ , i.e. the first vertex sits at coordinate  $e_1 := (1, 0, \ldots, 0)$ , the second sits at  $e_2 := (0, 1, 0, \ldots, 0)$ , and so on.<sup>1</sup> Then multiplying  $e_i$  with  $A_G$  maps a vertex *i* to the *sum* of all its neighbors in this space.

In the running example, if we start at  $e_1$ , then we move to its only neighbor, i.e.  $e_1A_G = e_2$ . But if we start at  $e_2$ , then we move to the sum of its neighbors, i.e.  $e_2A_G = (1, 0, 1) = e_1 + e_3$ .

What happens if we apply  $A_G$  a second time? Then we move to all "neighbors of neighbors". In the running example,  $e_2A_G^2 = (e_2A_G)A_G = (e_1 + e_3)A_G = e_1A_G + e_3A_g = 2e_2 = (0, 2, 0)$ . More generally, if we apply  $A_G$  multiple times, say t, this is equivalent to multiplying by the tth power of  $A_G$ , and we get a vector  $v \in \mathbb{R}^d$ , consisting of natural numbers, where the jth entry counts the number of paths (repeats allowed) from i to j.

Now, note that  $e_i A$  is the same as picking out the *i*th row of A. So this is equivalent to:

**Theorem 1.**  $A_G^t(i,j)$  is equal to the number of paths from *i* to *j* in the graph *G*, with repeated vertices allowed, of length exactly *t*.

Example/exercise: the undirected "bowtie" graph on 5 vertices where (1, 2, 3) is a cycle and (3, 4, 5) is a cycle. (In other words, two triangles, sharing a vertex 3.) Compute  $A_G^2$  and  $A_G^3$ , and check that this counts the number of walks.

Comment: For large graphs, exactly computing matrix multiplication can be computationally intensive, but this can be a useful algorithm as well as a stepping stone to more advanced or approximate techniques.

<sup>&</sup>lt;sup>1</sup>By default, we will assume vectors are row vectors, and write  $v^{\intercal}$  for their transpose, i.e. column vectors.

#### 1.2 The Normalized Adjacency Matrix

The **normalized** adjacency matrix is

$$W_G(i,j) = rac{1}{\operatorname{degree}(i)} A_G(i,j).$$

In other words, we normalize each row of  $A_G$  so that it sums to 1.

In the running example, we have

$$W_G = \begin{pmatrix} 0 & 1 & 0\\ \frac{1}{2} & 0 & \frac{1}{2}\\ 0 & 1 & 0 \end{pmatrix}$$

Now  $W_G$  maps a vertex to the *average* of all its neighbors in this space, i.e.  $e_i W_G = \frac{1}{\text{degree}(i)} \sum_{j:(i,j) \in E} e_j$ .

In the running example, if we start at the point  $e_1$  corresponding to vertex one, then we move to its only neighbor, i.e.  $e_1W_G = e_2$ . But if we start at  $e_2$ , we move to the midpoint between  $e_1$  and  $e_3$ , i.e.  $e_2W_G = \frac{e_1}{2} + \frac{e_3}{2} = (0.5, 0, 0.5).$ 

#### 1.3 As a Random Walk (Markov Chain)

Imagine you start at a vertex i of the graph and randomly select a neighbor (uniformly, with equal probability), and move to that neighbor. Then the row  $W_G(i)$  gives the induced probability distribution over these choices.

Indeed, if we have any vector  $v \in \mathbb{R}^n$  with  $v_i \ge 0$ ,  $\sum_{i=1}^n v_i = 1$ , this gives a probability distribution over the vertices of the graphs. Imagine sampling a vertex from that distribution, then randomly picking an edge and following it. What is the induced distribution on vertices? Well, the probability of landing on i is  $\sum_{j:(j,i)\in E} v_j \frac{1}{\text{degree}(j)} = (vW_G)_i$ . That is, the *i*th component of the vector we get from multiplying v into  $W_G$ .

So applying  $W_G$  to a probability distribution "evolves" the distribution by taking a further random step.

This is an example of a **Markov chain** on a finite state space with transition matrix  $W_G$ . In a Markov chain on a finite state space  $\{1, \ldots, n\}$ , we have a *transition matrix*  $M \in \mathbb{R}^{n \times n}$ , where M(i, j) is the probability of transitioning from i to j. Each row must be a probability distribution, i.e. nonnegative entries summing to 1. This says that, starting at i, we pick the next step of the random walk (or the next *state* of the Markov chain) from the probability distribution  $M(i, 1), \ldots, M(i, n)$ .

Next question: what happens if we iterate this random walk for a long, long time? I.e., what does the limit look like of  $vW_G^m$  as  $m \to \infty$ ? Does it matter what the starting distribution v is?

#### **1.4** Stationary Distributions and Eigenvalues

A stationary distribution  $\pi \in \mathbb{R}^n$  of a Markov chain with transition matrix M is a probability distribution satisfying

 $\pi M = \pi.$ 

In other words, if we draw a random vertex from  $\pi$ , then take a random step from the vertex, the distribution of our final endpoint is again  $\pi$ .

From linear algebra, we recall<sup>2</sup> such a vector is called a **left eigenvector** with corresponding **eigenvalue** 1.

The following are some basic facts about normalized adjacency matrices.

**Claim 1.** The largest left eigenvalue of  $W_G$  is exactly 1, and the smallest is at least -1 (which is achieved if and only if G is bipartite). The multiplicity of 1, i.e. the number of eigenvalues that are 1, is equal to the number of connected components of the graph.

<sup>&</sup>lt;sup>2</sup>In general we have a left eigenvector v with eigenvalue  $\lambda$  if  $vW_G = \lambda v$ .

Given a transition matrix M, we name its n eigenvalues  $\{\lambda_i\}$  and sort them from largest to smallest:  $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n$ .

The list  $\lambda_1, \ldots, \lambda_n$  is called the **spectrum** of M; this is why this area of research is called "spectral" graph theory.

#### **1.5** Convergence to Stationary

Next, we will make some strong assumptions that imply there is exactly one stationary distribution and the distribution of a random walk, over a long time horizon, converges to it. This is just an example to show the flavor of these theorems and proofs in spectral graph theory; most such proofs are a bit more intricate and advanced, usually going to a related matrix called the graph Laplacian (which we won't need here).

**Claim 2.** Suppose that every entry of the transition matrix M is strictly positive; then its eigenvalues satisfy  $\lambda_1 = 1$  and  $|\lambda_i| < 1$  for all i = 2, ..., n.

Now consider starting from some distribution  $p^{(0)}$  over the vertices and repeatedly applying a transition matrix M, so that after t steps, we get  $p^{(t)} := p^{(0)}M^t$ .

**Theorem 2.** Suppose every entry of the transition matrix M is strictly positive and suppose that M is a diagonalizable matrix. Let  $\sigma = 1 - \max_{i=2,...,n} |\lambda_i|$ . Then there exists a constant C such that for all t, we have

$$\|\pi - p^{(t)}\|_1 \le C \cdot n \cdot e^{-t\sigma}.$$

(Recall that  $||x||_1 = \sum_i |x(i)|$ .)

*Proof.* Let the eigenvectors of M be  $\pi, x_2, \ldots, x_n$  and suppose without loss of generality that each vector has  $||x_j||_1 = 1$ . Because M is diagonalizable, its eigenvectors  $\pi, x_2, \ldots, x_n$  span all of  $\mathbb{R}^n$ , i.e. they are linearly indpendent (note we are not assuming they are orthogonal!). So any starting point  $p^{(0)}$ , we can write it as a linear combination of eigenvectors  $\pi, x_2, \ldots, x_n$ :

$$p^{(0)} = c_1 \pi + \sum_{j=2}^n c_j x_j.$$

Note the coefficients  $c_i$  may be positive or negative. Then

1

$$p^{(t)} = p^{(0)} M^t$$
$$= \left( c_1 \pi + \sum_{j=2}^n c_j x_j \right) M^t$$
$$= c_1 \pi + \sum_{j=2}^n c_j x_j \lambda_j^t.$$

Now, we argue that  $c_1 = 1$ . Because we have  $|\lambda_j| < 1$  for  $j \ge 2$ , the entire sum is converging to  $\vec{0}$  as  $t \to \infty$ . So we have  $p^{(t)} \to c_1 \pi$ , and because both are probability distributions, we must have  $c_1 = 1$ . So

$$p^{(t)} = \pi + \sum_{j=2}^{n} \alpha_j x_j \lambda_j^t.$$

Therefore, if we let  $C = \max_{j=2,\dots,n} |c_j|$ , then

$$\begin{aligned} \|\pi - p^{(t)}\|_{1} &= \left\| \sum_{j=2}^{n} c_{j} x_{j} \lambda_{j}^{t} \right\|_{1} \\ &\leq \sum_{j=2}^{n} |c_{j}| \cdot |\lambda_{j}|^{t} \cdot \|x_{j}\|_{1} \\ &\leq \sum_{j=2}^{n} C(1 - \sigma)^{t} \\ &\leq C \cdot n \cdot (1 - \sigma)^{t} \\ &\leq C \cdot n \cdot (1 - \sigma)^{t} \\ &\leq C \cdot n \cdot e^{-\sigma t}, \end{aligned}$$
 because  $\|x_{j}\|_{1} = 1$ 

To step back and appreciate this theorem: Even if the number of vertices of the graph is gigantic, say  $n = 2^d$  for some d, we can get convergence very close to the stationary distribution in only  $O(d/\sigma)$ steps of the random walk. As long as  $\sigma$  isn't too tiny, this is quite few compared to n.

#### 1.6 PageRank

The key idea of PageRank is to let G be the directed graph of hyperlinks on the web, where each vertex is a webpage with edges to every page it has links to.

Now we can imagine the Markov chain (random walk) of the normalized adjacency matrix  $W_G$ . But in PageRank, we make the following modification: with probability  $\alpha$ , we jump to a new, completely uniformly random webpage. With probability  $1 - \alpha$ , we follow a random link on the current page.

This gives rise to the following transition matrix:

$$M(i,j) = \frac{\alpha}{n} + (1-\alpha)W_G(i,j).$$

One nice consequence is that, for  $\alpha > 0$ , every entry is strictly positive and there is a unique stationary probability distribution  $\pi$  of this random walk. This is the **PageRank** of G.

In particular, for each page i, its rank or score is  $\pi(i)$ , with larger being better.

 $\pi$  has the following nice property, inherited from the equation  $\pi M = \pi$ :

$$\pi(j) = \sum_{i=1}^{n} \pi(i) M(i, j)$$
$$= \frac{\alpha}{n} + (1 - \alpha) \sum_{\substack{i:(i,j) \in G \\ \text{degree}(i)}} \frac{\pi(i)}{\text{degree}(i)}.$$

This says the asymptotic probability of being on page j is the sum of two processes:

- With probability  $\alpha$ , no matter where we are, we jump randomly, in which case there is a  $\frac{1}{n}$  chance of landing on page j.
- With probability  $1 \alpha$ , we are on page *i* with probability  $\pi(i)$ , and we jump to page *j* with probability  $\frac{1}{\text{degree}(i)}$  if there is a link (i, j).

Now, with billions of webpages, we cannot even store G in memory as an adjacency matrix, let alone compute its powers exactly, but we still have ways to approximately sample from  $\pi$ ; we'll look at this next.

## 2 Markov Chain Monte Carlo

We now will look briefly at a more general, powerful technique. The idea is that we need to sample or estimate an integral from a challenging distribution over a very large space. We can't write down the distribution, but we have some info about it.

For example, suppose we want to sample a web page with probability proportional to the number of words on the page. So if f(j) is the number of words on page j, we want  $\pi(j) = \frac{f(j)}{\sum_i f(i)}$ . But the denominator is expensive to compute.

(This can be extended to compute an expectation or integral of some function with respect to this difficult distribution.)

**Claim 3.** Let  $p^{(0)}$  be any distribution and  $p^{(t)} = p^{(0)}M^t$ , where M is the transition matrix of a Markov chain. If M is connected (meaning any state i is reachable from any state j), then it has a unique stationary distribution  $\pi$ , and as  $t \to \infty$ , the average  $\frac{p^{(1)}+\dots+p^{(t)}}{t}$  converges to  $\pi$ .

**Lemma 1.** For a Markov chain with transition matrix M, if strongly connected, if there exists a distribution  $\pi$  satisfying

$$\pi(i)M(i,j) = \pi(j)M(j,i),$$

then  $\pi$  is the unique stationary distribution.

Note that this does not claim the stationary distribution always satisfies this relationship. For example, in some graphs we may have M(i, j) > 0 while M(j, i) = 0, so it is impossible to satisfy.

## 2.1 Metropolis Hastings

For a running example, think of a grid of points in high dimensional space, for example, the Boolean hypercube  $\{0,1\}^k$ . (In other words, each "vertex" is labeled by a string of length k of zeros and ones; there are  $2^k$  vertices.)

For this algorithm, we suppose that someone gives us a likelihood or weight function  $f : \{1, \ldots, n\} \rightarrow \mathbb{R}_+$ , and asks us to sample points with probability proportional to f. So in this case we know the probability distribution at each state u: it is

$$\pi(u) := \frac{f(u)}{\sum_{v} f(v)}.$$
(1)

The problem is that n is too large to compute the sum efficiently (and even if we knew it, it's still not obvious how to sample).

The idea is that we can construct an undirected graph on  $\{1, \ldots, n\}$  and run a Markov chain that converges to this stationary distribution  $\pi$ , without ever writing down  $\pi$ .

The first step is to come up with a graph. We want the following properties, for reasons we'll see.

- We want the *mixing time* to be small, meaning that the random walk converges fast.
- We want the maximum degree, call it r, to to be relatively small.
- We want vertices to have edges to other vertices with similar "weight" f(v).

For the Boolean hypercube example, perhaps we create an edge (u, v) if we can get from u to v by flipping one bit of the string. In some applications, it's reasonable that if u and v are the same string except for one bit, then their weights f(u), f(v) aren't too different. The maximum degree is also only k if we are in k dimensions, which is much smaller than the total number of vertices  $2^k$ .

Algorithm 1 gives a Markov chain with

$$M(u,v) = \frac{1}{r} \min\left\{1, \frac{f(v)}{f(u)}\right\}.$$

**Theorem 3.** The stationary distribution of the Markov chain with transition matrix M is  $\pi$  (Equation 1).

Algorithm 1 Metropolis-Hastings on finite graph. The goal is to sample vertices with probability proportional to f.

- 1: Input: oracle access to  $f : \{1, \ldots, n\} \to \mathbb{R}_+$ ; oracle access to adjacency list of G on vertices  $\{1, \ldots, n\}$ ; maximum degree r of G.
- 2: Let  $u^{(0)}$  be chosen uniformly at random from  $\{1, \ldots, n\}$
- 3: for some number of trials  $t = 1, \ldots, T$  do
- Let  $v_1, \ldots, v_\ell$  be the  $\ell$  neighbors of  $u^{(t-1)}$ 4:
- Let  $v = \begin{cases} v_i & \text{w.prob. } \frac{1}{r} \\ u^{(t-1)} & \text{w.prob. } \frac{r-\ell}{r} \end{cases}$ 5:
- if  $f(v) \ge f(u^{(t-1)})$  then Set  $u^{(t)} = v$ . 6:
- 7:

else 8: Set  $u^{(t)} \begin{cases} v & \text{w.prob. } \frac{f(v)}{f(u^{(t-1)})} \\ u^{(t-1)} & \text{o.w.} \end{cases}$ . 9: end if 10: 11: end for

*Proof.* We just need to verify that the conditions of Lemma 1 are satisfied by the target distribution  $\pi$ . Consider any edge (u, v) and suppose without loss of generality that  $f(u) \ge f(v)$ . Then  $M(u, v) = \frac{1}{r} \frac{f(v)}{f(u)}$ . while  $M(v, u) = \frac{1}{\pi}$ .

So  $\pi(u)M(u,v) = \frac{f(u)}{\sum_{u'}f(u')}\frac{1}{r}\frac{f(v)}{f(u)} = \frac{f(v)}{r\sum_{u'}f(u')}.$ Meanwhile,  $\pi(v)M(v,u) = \frac{f(v)}{\sum_{u'}f(u')}\frac{1}{r}.$ These are equal, so the conditions of Lemma 1 are satisfied.

To conclude: Metropolis-Hastings gives us a general way to construct a Markov chain such that, if we sample from it, it converges to the target distribution  $\pi$  that we wanted to sample from. Of course there are lots of design questions left: how to chose the graph G and when you are able to access such a function f. The answers to these vary depending on the problem being solved in practice.
